Cardano Software Engineering Assignment

Context

Cardano has advanced business teams who can create Python software to perform their own self-service calculations and simulations. In this case, we would like to have a process that takes in transactions data from various sources and combines them in a unified format so that in can be available to other teams and processes at Cardano. It is your choice how that software is designed and set up – including how the output data is accessible. The output data should contain everything in the input datasets plus additional information if necessary.

Requirements

- Accept three different datasets as input in **CSV, JSON, and XML** formats.
- Convert all monetary values to **EUR**, based on the exchange rates provided in the datasets.
- Store the output dataset preferably in **SQLite** (or **CSV** if its unfeasible for you to do it in SQLite), making it available for further use.

Execution & Instructions

Provide clear instructions on how to run the application. We should have everything needed for us to be able to run your software locally.

Submission

Please submit your solution via an online platform such as GitHub instead of an email with attachments as it can get blocked by our servers due to potential malicious content.

Disclaimer

When executing this assignment, you will make several engineering choices as you would normally do during any SDLC during your employment. These choices should be taken as you would normally do if this were a production system ready to deliver – including stability, resilience, robustness, failure management – but adapted to the time slot of this assignment. You will have the opportunity to explain and debate such choices. However, its deployment and execution can remain local on your machine. We are constraining you on one choice: use Python. Also note that all the information in the input data are randomized and anonymized.

Good luck!
